### THE EXTERNAL ANATOMY OF THE PRIMITIVE TANYDERID DIPTERAN MACROCHILE SPECTRUM LOEW, PRESERVED IN BALTIC AMBER.

BY G. C. CRAMPTON, PH.D., Massachusetts Agricultural College,  
Amherst, Mass.

Through the kindness of Frau Dr. Richard Klebs, Fraulein Dr. Elizabeth Skwarra, and Professor Dr. K. Andréé, the amber Tipulids of the Klebs Collection, and those of the Koenigsberg Geological Institute, were recently sent to Dr. C. P. Alexander for study; and in this material were practically all of the known specimens of the extremely interesting and primitive Dipteran *Macrochile spectrum* Loew. Since there were enough specimens of *Macrochile* for me to be able to make out, in some of them, all of the main features of both sexes, I was delighted to accept Dr. Alexander's suggestion that I make a detailed study of the external features of this interesting and important insect, which has departed but little, in many respects, from the condition characteristic of the ancestral Diptera.

One would have to do considerable "restoring" in attempting to reconstruct the external form of the fossil three- and four-toed horses (such as *Protorohippus*, *Epihippus* and *Mesohippus*) and other extinct Mammalian contemporaries of *Macrochile* in the upper Eocene and lower Oligocene epochs (calculated at between thirty and forty million years ago by Dr. A. C. Lane); but since the hard parts of *Macrochile* are external, and since the imprisoning and preserving gum in which the specimens were imbedded has hardened into a transparent mass, which is beautifully clear in the fine mounts from the above-mentioned collections, it is possible, with a little manipulation, to make out all of the external

details of both sexes, in the long-extinct *Macrochile*—and in examining such well-preserved material, it is indeed difficult to realize that one is not dealing with balsam mounts of recently collected specimens! In spite of the excellent preservation of these insects, however, I do not know of any serious attempt to figure all of the essential external features of both sexes of any fossil insect whatsoever, and on this account it may be of some interest to present the principal external features of both sexes of this primitive Dipteran, which is in many respects one of the most interesting and important representatives of the order thus far known.

As is shown in Figs. 2 and 3, the males of *Macrochile* are holoptic, and the females are dichoptic. Dr. Alexander has called my attention to the fact that hairs occur between the facets of the ommatidia of the compound eyes in all Tanyderids, and he also called my attention to the presence of such hairs between the facets of the eyes of *Macrochile*, thus adding further proof to that from other sources indicating that *Macrochile* is a true Tanyderid—though it is very like the common ancestor of the Psychodids, Tanyderids, and Ptychopterids in some respects. In fact, *Macrochile's* thoracic structures are so annectant between those of the three other families mentioned that I have no hesitancy in grouping the Psychodids, Tanyderids and Ptychopterids in a single superfamily, the Psychodoidea, following a suggestion made by Dr. Edwards (see Crampton, 1926).

As in all other Psychodoids, the ocelli are wanting in *Macrochile*. The antennae are composed of nineteen segments in both sexes, and are much like those of *Tanyderus*. In the antenna of the female *Macrochile* shown in Fig. 13, the postpedicel *ppd*, or third segment of the antenna, is unusually long, and gives the appearance of being the fusion product of two segments. In the antennae of this female, however, there were nineteen antennal segments as in the antennae of the males, which have a shorter postpedicel (Fig. 14, *ppd*), so that the abnormally long postpedicel of the female shown in Fig. 13 is apparently not the result of the fusion of two antennal segments. The proportions of the other segments of the antenna do not differ greatly in the two sexes, so that Fig. 13 will serve to illustrate a typical antenna, with the exception of the segment labelled *ppd*.

The heads of the females shown in Figs. 1 and 3 are somewhat "foreshortened," since I was unable to see the heads properly

(due to the refraction of light when the surfaces of the amber were turned at too great an angle to the source of illumination) when the amber blocks were tilted enough to bring the heads into a horizontal plane, in looking at them from above, so that the mouth-parts are not represented as long as they should be in proportion to the breadth of the head. On the other hand, the base of the proboscis is usually retracted within the mentum bearing the label *mn* in Fig. 1, in *Macrochile*, as in other Tanyderids, and in the male *Macrochile* shown in Fig. 2, the proboscis is unusually extended.

In an article dealing with the labium of the Holometabola (Crampton, 1925), I have given a figure (Fig. 3 of the paper in question) of the labium of *Tanyderus*, with which the labium of *Macrochile* here shown (Fig. 1) may be compared. In *Macrochile* (Fig. 1), the labella *lbl*, or modified distal segments of the labial palpi, are rather sharply demarked from the basilabella *blb*, or basal segments of the palpi, in the ventral view of the labium shown in Fig. 1; but in the lateral view of the labium shown in Fig. 2, the basal segments of the palpi are not very clearly demarked, due to the rather poor condition of the specimens showing this aspect of the labium. As may be seen in Figs. 2 and 17, the labella *lbl* form a trough into which the labrum *lr* may lie—or its distal portion, at least, is usually overlapped by the labella laterally. The region *pgr* of the underlip of *Macrochile* (Fig. 1) represents the united palpigers; and the incomplete suture between the palpigers of *Tanyderus* has almost completely disappeared in *Macrochile*, in which barely the faintest trace of it can be detected if the lighting is "just right" to bring it out. The elongated sclerite bearing the labels *mn* and *sm* in Fig. 1, represents the united mentum and submentum (and is probably largely composed of the mentum) as was pointed out by Crampton, 1925; and in *Macrochile* this sclerite is somewhat broader, and therefore more primitive, than in the labium of *Tanyderus* shown in the paper mentioned above. The labium of *Macrochile*, as a whole, is more primitive than that of *Tanyderus*, and it is possible that the small area at the bases of the sclerites labelled *blb* in Fig. 1, represent traces of the missing third, or true basal, segment of the labial palpi; and if this is the case, *Macrochile* has preserved the rudiments of the basal segments of the labium which are completely lost in every Dipteran I have examined. There were some indications of a thickening and deposit of pig-

ment in the area labelled *gu* in Fig. 1, which might be interpreted as a tendency to form a gular region in *Macrochile*.

Due to the fact that there was a great deal of refraction of light when the blocks of amber were tilted at a sharp angle to the rays of light from the lamp used to illuminate the field of the dissecting microscope, I could make out practically nothing of the maxillary structures excepting the maxillary palpi *mxp* of Figs. 1, 2, and 3. The maxillary palpi appear to be composed of five segments, although it is possible that the small basal segment may represent the palpifer. I am more inclined to think that the palpifer is contained in the region at the base of the segment in question, however, so that the maxillary palpi are probably five-segmented.

As is shown in Fig. 17, the labrum *lr* (which probably represents the so-called labrum-epipharynx) is bent somewhat, so as to lie at a different level from that of the fronto-clypeus *fc*. The region labelled *fc* in Figs. 2 and 3, probably represents the united frons and clypeus, and is therefore referred to as the frontoclypeus, although it would perhaps be simpler to call it simply the frons. Behind the region *fc* in Fig. 3 is a bridge-like area, which is not clearly seen in most specimens. This area separates the frons *fc* from the parietal region *pa* usually referred to as the vertex. Posterior to the parietal region *pa* is the small occiput *oc* or "nape," which is extremely difficult to make out in the specimens available to me.

On each side of the occiput *oc* of Fig. 3 is a bulging structure *alc* (see also *alc* of Fig. 2) which probably represents the sclerite called the precervicale, or anterior lateral cervical plate, in other Diptera. This area is somewhat larger than in other Tanyderids, and is rather imperfectly chitinized and pigmented. The lateral cervical sclerite *lc* is somewhat smaller than it is in other Tanyderids (it is extremely elongated in *Tanyderus*) and I experienced considerable difficulty in making out the outlines of this sclerite in the specimens available to me, so that I am not entirely sure of its exact appearance, although it seemed to have an elongated anterior process (called the cephaliger) extending forward to the occipital condyles of the head. The appearance of the sclerites *lc* is better shown in Fig. 2 than in Fig. 1, since the parts were considerably distorted in the insect shown in Fig. 1, as is also the case in Fig. 3, in which the neck region is represented as though it were much broader than is the case with more normal specimens.

In Fig. 1 is shown the presternum *ps* or anterior sclerite of the prosternal region, and a portion of the second sternal plate, or basisternum, is labelled *bs* in Fig. 1. I could make out practically nothing else of the sternal region of the prothorax in my material, but by combining parts visible in several specimens, it was possible to reconstruct the lateral portions of all of the thoracic segments very satisfactorily, especially since I had been working on this part of the body in lower Diptera recently, and was therefore more familiar with the parts in closely allied forms, and could therefore tell what to look for in *Macrochile* to better advantage.

I have already discussed the thoracic structures of *Macrochile* in a paper which will soon be published (Crampton, 1926) dealing with the thoracic structures of the Psychodoidea in general. It will therefore not be necessary to do more than to call attention to some of the more interesting features of *Macrochile's* thorax, at this time. The pronotum *apn* and *ppn* of *Macrochile* (Fig. 5) is narrower than that of the other Tanyderids I have examined, and in this respect *Macrochile* is intermediate between the rest of the Tanyderids and the Bruchomyine Psychodids, and it is much nearer the Ptychopterid type than is the case with the pronota of other Tanyderids. The same may be said of the rather elongated coxae and the more elongated (dorso-ventrally) thoracic contour of *Macrochile*, since in these respects *Macrochile* is intermediate between the rest of the Tanyderids and the Bruchomyine Psychodids (such as *Bruchomyia* and *Nemoplapus*), and it is approached by the thorax of *Ptychoptera* in this respect. The metanotum *mtn* of *Macrochile* (Fig. 5) is likewise intermediate in character between the Tanyderid type and the Psychodid type (exemplified by *Phlebotomus*). As is shown in Fig. 15, the metanotum *mtn* becomes narrowed mesally, as does that of the Psychodid *Phlebotomus*, while the lateral portions remain somewhat "oval" as in *Phlebotomus*.

In *Macrochile*, as in all other representatives of the superfamily Psychodoidea, the meron of the mesothoracic coxa unites with the lower portion of the mesothoracic epimeron to form the area *mpl*, of Fig. 5; and the suture *a* is incomplete as in all Psychodoids. As in all members of the Psychodoidea, there is a rather clearly demarked area *saf* in Fig. 5 of *Macrochile*. The well-known "V-shaped" suture familiar to all students of the Tipulids is incomplete in *Macrochile* (i.e., the suture labelled *s* in Fig. 5), and the metathoracic spiracle *sp* is very near the base of the halter in *Macrochile*, as in all of the Psychodoidea.

The relative lengths of the various segments of the legs are shown fairly accurately in Figs. 19 and 20, and there is nothing strikingly different in them from the structures to be found in *Tanyderus* and similar forms. It may be noted in passing, that there are two movable spines at the apex of the hind tibiae (Figs. 18 and 19); and the pulvilli, empodium, and other structures of this nature are undeveloped, as in most lower Diptera. The claws *un* of Fig. 16 are rather interesting, but do not differ markedly from those of *Tanyderus*.

Of the other thoracic appendages there remain to be considered only the wings and halteres. The venation, as is shown in Fig. 11, is of an extremely primitive type, and the character of the median veins would indicate that the view of Dr. Tillyard as to the four-branched character of *media* is the correct one. I have therefore adopted Dr. Tillyard's interpretation of the primitive Dipterous venation in homologizing the veins of *Macrochile* shown in Fig. 11, with the exception of the vein labelled *pa*, which Tillyard considers as the second branch of *Cu* in related insects, but which appears to be an intermediate vein, the preanal, regarded by some investigators as the first anal, by others as the second branch of *Cu*. I prefer to refer to it simply as the preanal vein, since its true relations to the other veins have not been definitely determined. I could not detect any connection between the base of this preanal vein and the cubital or anal veins, in *Macrochile*, but in *Tanyderus forcipatus* the base of the preanal vein seems to dip down to the first anal, although the vein is so faint in this region that I cannot be sure in the matter. The anal veins behind the large first anal were greatly reduced, and were very difficult to make out, but they seem to be of the general character of the veins behind the first anal in *Tanyderus*, so far as I can make them out. The longitudinal veins bear numerous macrotrichiae, but it would obscure the course of the veins to attempt to indicate the occurrence of the macrotrichiae, so that they have been omitted in the figure. I noted macrotrichiae on the membrane of the wing in several instances, but apparently these were detached macrotrichiae which chanced to come to rest upon the wing membrane before the gum hardened into amber.

Dr. Alexander has called to my attention the fact that the cross vein *m* (Fig. 11) is present in all Tanyderids, and that *Macrochile* is clearly an "out and out" Tanyderid on this account, although I was inclined to consider *Macrochile* as rather near the

Psychodid *Bruchomyia* because of the great similarity between the two in certain thoracic features, which, however, were not sufficiently important to outweigh the evident similarities between *Macrochile* and *Tanyderus* in the nature of the head, mouthparts, and other features.

In their general venational characters, *Bruchomyia* and the Tanyderids have so much in common, that Dr. Alexander formerly included *Bruchomyia* in the family Tanyderidae—although, of course, later studies have shown that *Bruchomyia* is a Psychodid. Dr. Alexander's grouping, however, apparently gave the hint to Dr. Edwards who suggested (*in litteris*) that the Psychodids (including *Bruchomyia*), Tanyderids and Ptychopterids should be included in a single superfamily; and as soon as I began the study of *Macrochile* (Crampton, 1926) the synthetic character of its thoracic sclerites at once convinced me that the Psychodids, Tanyderids and Ptychopterids intergrade and should be united in a common superfamily, the Psychodoidea. The venational evidence supports that of the thoracic sclerites, so that all of the structures thus far studied clearly indicate that the three families mentioned should be grouped in a single superfamily.

There are a few peculiar features in the venation of *Macrochile* which are difficult to interpret. Thus, the stub of a vein at the anterior end of the cross vein *r-m* is a very puzzling feature which is also present in specimens of *Bruchomyia*, *Tanyderus*, and *Protoplasa*, so that it may have some phylogenetic significance. A fold-like line in this region may indicate the beginning of the formation of the structure which develops into the so-called spurious vein in Syrphidae, and this matter would repay further investigation along these lines.

The stub of a vein projecting beyond (distally) the forking of *Sc* is another puzzling feature which I do not understand. It was present in one specimen of *Macrochile* but was absent in all of the other specimens examined. This stub may possibly represent the true first branch of *Sc*, and in that case, the vein I have labelled *Sc*<sub>1</sub> in Fig. 11 would be merely a cross vein. This suggestion is offered for what it is worth, since I have not been able to investigate the subject further.

The halter (Fig. 12) presents no features of especial interest, although the nature and location of the projection labelled *p* in Fig. 5 suggests that this structure may be the precursor of the so-called prehaltere or spatulate appendage in front of the base of the halter in Ptychopterids.

There are no features in the basal region of the abdomen requiring especial mention, save the fact that in the specimen shown in Fig. 15, the abdomen was bent sharply downward, exposing a rather large intersegmental membrane or conjunctiva *cnj*, which is of somewhat greater extent than in most Tanyderids.

The terminal structures are the most important parts of the abdomen, since these offer characters of specific value, and fortunately, it was possible to make out practically all of the structural details of both sexes in the material available to me. I have therefore given figures of the dorsal, lateral and ventral aspects of the male and female.

The eighth abdominal segment of the female (Figs. 6, 8, and 9) is not greatly reduced as is the case with the eighth segment of the male (Figs. 4, 7, and 10), and the eighth sternite of the female bears a pair of projections labelled *vv* in Figs. 8 and 9. From their position, one might infer that these projections represent the ventral valves of the ovipositor of lower Holometabola, but I am more inclined to consider them as the homologues of the valvular processes of the hypogynium, or subgenital plate of the female in other insects. I was unable to find similar structures in the females of *Tanyderus* or *Protoplasa*, and it is possible that *Macrochile* is the only Tanyderid in which they occur.

Another peculiar structure occurring in *Macrochile* is the structure labelled *mg* in Figs. 8 and 9. It would be interesting to trace the origin of this structure in order to determine if it has any relation to the dorsal valves of the ovipositor in lower Holometabola, although I doubt that any such relation exists, and it is more probable that the structure in question is merely an outgrowth of the sternal region.

The basal segments of the cerci labelled *bc* in Figs. 6, 9, and 8 are peculiar in shape, and bear rather sharply pointed ventral processes projecting posteriorly. If the structures labelled *bc* are not the basal segments of the cerci, they probably represent the paraprocts or parapodial plates, which are in reality modified basal segments of the cerci, although they are not usually recognized as such. If the structures labelled *bc* are the parapodial plates, the structures labelled *dc* are the cerci, instead of representing merely the distal segments of the cerci, as the labelling would indicate.

The precerci, or sclerites bearing the label *cg* in Figs. 6 and 8, possibly represent the tenth, or the united tenth and eleventh seg-

ments, but the homologies of the parts are not clear, and there is evidently considerable need of a thorough study of the terminal structures of both sexes of the Pterygota in general, beginning with the Orthopteroid forms, and including all of the higher types of insects as well.

The ninth tergite *epa* of the male (Figs. 7 and 10) is much larger than the ninth tergite of the female (Figs. 6 and 8), and the cerci of the male are apparently composed of but one segment, so that the structure labelled *bc* in Fig. 10 apparently corresponds to the structure labelled *bc*, alone, in Fig. 8. The anus-bearing structure *pg* is more easily seen in the male (Figs. 7 and 10) than in the female. It probably represents the eleventh segment, although this has not been definitely determined.

The gonostyli or stylus-like claspers of the male insects are usually composed of two segments in the Holometabola related to the Diptera. In the males of *Macrochile*, the basal segments or basistyles *bst* of Figs. 4 and 7 unite basally, or fuse with the neighboring parts as shown in Fig. 4. The dististyles or distal segments of the claspers labelled *ds* in Figs. 4 and 7 bear median projections and outgrowths which are of considerable interest.

As is shown in Figs. 4 and 7, the dististyles *ds* are forked, and the basal process *sap* probably represents the precursor of the basal or inner appendage of the dististyle in other Diptera, while the distal process *ap* probably represents the outer or apical appendage of the divided dististyle of other Diptera. The forking of the dististyle in *Macrochile*, therefore, probably foreshadows the division of the dististyle into an inner and outer appendage in other Diptera. Between the forks of the dististyle is a projection *iap* (Figs. 4 and 7) which is small and difficult to see clearly.

Since *Macrochile* is such a primitive Dipteran in many respects, I had hoped that the condition of the genital styles in it might give some hint of the nature of the genital styles in Diptera in general, but these structures are too highly modified even in *Macrochile* to be of much use in this respect. It is possible that the genital styles of the Holometabola related to the Diptera may not be homologous with the styli of Orthopteroid males, but the genital styles of these Holometabola may still be called gonostyli, since they are style-like appendages of the genitalia, and the true styli of male Orthopteroid insects might be differentiated from these by calling them androstyli, or simply styli.

The aedeagus *aed* of *Macrochile* (Figs. 4 and 10) appears to

be bifid, or it is composed of two parts. Paired projections labelled *gap* in Figs. 10 and 7, flank a central structure which is very difficult to make out because the amber in this region is very much clouded (due to the inclosure of moisture, etc.) in all of the specimens examined. The structures labelled *gap* in Figs. 7 and 10, are provisionally termed the "gonapophyses," although this designation is not as appropriate as certain other terms applied to similar structures.

From the foregoing discussion, it is quite apparent that a detailed study of the external morphology of insects preserved in amber can be made with considerable accuracy and ease, and it is to be hoped that more of the amber insects will be figured in detail, so that their principal anatomical features may be made available for comparison with the structures of living forms, since the amber insects are in many instances more primitive than recent insects; and when they represent synthetic types, as is the case with *Macrochile*, the study of their anatomy is of the greatest interest and importance from the standpoint of phylogeny.

## ABBREVIATIONS.

A	Anal vein.	aei	Anepisternal incision or cleft.
a	Arculus in wing veins.		
a	Anepisternal suture in thorax.	aem	Anepimerum or pteropleurum.
aed	Aedeagus.	aes	Anepisternum.

alc	Precervicale.	mxp	Maxillary palpus.
ant	Antenna.	nm	Notomacula.
ap	Apical or outer process.	oc	Occiput.
apn	Antepronotum.	p	Prehaltere.
b	Anepimeral suture.	pa	Parietal region or vertex of head.
bc	Basicercus (paraproct?).	pa	Preal vein of wing (Cu <sub>2</sub> according to Tillyard, 1st A of Comstock).
blb	Basilabella.	pas	Parascutellum or axilla.
bs	Basisternum of prothorax.	pat	Paratergite.
bst	Basistyle.	pd	Pedicel.
bta	Basitarsus ("metatarsus").	pg	Proctiger.
c	Pleural suture.	pgr	Palpiger.
cg	Precercus.	ppd	Postpedicel.
cnj	Conjunctiva.	ppn	Postpronotum.
Cu	Cubitus.	ps	Presternum of prothorax.
cx	Coxa.	psc	Prescutum.
dc	Disticercus.	psl	Postscutellum.
ds	Dististyle.	pt	Postalare or Pleurotergite.
dta	Distitarsus.	R	Radius.
ec	Eucoxa.	R <sub>s</sub>	Radial sector.
em	Epimerum.	r-m	Radio-medial cross-vein.
epa	Epandrium (9th tergite of male).	s	Scutal suture.
es	Episternum.	saf	Subalifer.
fc	Frontoclypeus.	sal	Subalare.
fe	Femur.	sap	Basal process of dististyle.
gap	Gonapophysis.	Sc	Subcosta.
ge	Gena.	sc	Scutum.
gu	Gula.	sca	Scape.
h	Humeral cross-vein.	sl	Scutellum.
iap	Intermediate process.	sm	Submentum.
lc	Laterocervicale.	sp	Spiracle (metathoracic).
lbl	Labellum.	spl	Sternopleurum.
lr	Labrum or labrum-epipharynx.	ta	Tarsus.
M	Media.	ti	Tibia.
m	Median (intermedian) cross-vein.	tr	Trochanter.
m-cu	Medio-cubital cross-vein.	tsp	Tibial spurs.
mg	Mediognium.	un	Claws or ungues.
mn	Mentum.	vv	Hypogynial valves.
mpl	Meropleurum.		
mt	Mediotergite.		
mtn	Metanotum.

## EXPLANATION OF PLATES.

- Fig. 1. Ventral view of head of female (slightly tilted upward).  
Fig. 2. Lateral view of head of male viewed somewhat obliquely.  
Fig. 3. Dorsal view of head of female (tilted downward).  
Fig. 4. Ventral view of terminal abdominal structures of male.  
Fig. 5. Lateral view of thorax.  
Fig. 6. Dorsal view of terminal abdominal structures of female.  
Fig. 7. Dorsal view of terminal abdominal structures of male.  
Fig. 8. Lateral view of terminal abdominal structures of female.  
Fig. 9. Ventral view of terminal abdominal structures of female.  
Fig. 10. Lateral view of terminal abdominal structures of male.  
Fig. 11. Dorsal view of right wing.  
Fig. 12. Dorsal view of right halter.  
Fig. 13. Ventral view of right antenna of female.  
Fig. 14. Basal segments of male antenna viewed obliquely dorsally.  
Fig. 15. Dorsal view of metanotum and first tergite.  
Fig. 16. Lateral view of tip of left tarsus of male.  
Fig. 17. Lateral view of terminal portion of trophi of male.  
Fig. 18. Lateral view of right hind tibia of male.  
Fig. 19. Lateral view of hind leg.  
Fig. 20. Lateral view of left fore leg of male.

N. B.—The subscripts 1, 2, and 3 indicate that the part in question belongs to the pro-, meso-, or meta-thorax. The letter *t* written to the right and above a numeral indicates the tergite of the segment indicated by the numeral. The letter *s* indicates the corresponding sternite.

---

**A Correction.**—In his paper "Studies of North American Aegeriidae, No. 3," BULLETIN, vol. XX, no. 4, p. 157, the author omitted to state the locality for the Holotype of *Alcathoe pepsioides*. It is Durango, Colo. The spelling of the specific name of the food-plant, "*Clematis ligustrifolia*," also should be corrected to read "*ligusticifolia*." Dr. T. D. A. Cockerell has been good enough to call attention to this omission and error.—GEO. P. ENGELHARDT, Brooklyn Museum.
